

A Third Look At ML

Outline

- More pattern matching
- Function values and anonymous functions
- Higher-order functions and currying
- Predefined higher-order functions

More Pattern-Matching

- Last time we saw pattern-matching in function definitions:
 - `fun f 0 = "zero"`
 `| f _ = "non-zero";`
- Pattern-matching occurs in several other kinds of ML expressions:
 - `case n of`
 `0 => "zero" |`
 `_ => "non-zero";`

Match Syntax

- A *rule* is a piece of ML syntax that looks like this:

$$\langle rule \rangle ::= \langle pattern \rangle \Rightarrow \langle expression \rangle$$

- A *match* consists of one or more rules separated by a vertical bar, like this:

$$\langle match \rangle ::= \langle rule \rangle \mid \langle rule \rangle \mid \langle match \rangle$$

- Each rule in a match must have the same type of expression on the right-hand side
- A match is not an expression by itself, but forms a part of several kinds of ML expressions

set of rules

Case Expressions

```
- case 1+1 of
=      3 => "three" |
=      2 => "two"  |
=      _ => "hmm" ;
val it = "two" : string
```

- The syntax is

<case-expr> ::= case <expression> of <match>

- This is a very powerful case construct—unlike many languages, it does more than just compare with constants

Example

```
case x of
  _ :: _ :: c :: _ => c |
  _ :: b :: _      => b |
  a :: _           => a |
  nil              => 0
```

The value of this expression is the third element of the list **x**, if it has at least three, or the second element if **x** has only two, or the first element if **x** has only one, or 0 if **x** is empty.

Generalizes **if**

```
if  $exp_1$  then  $exp_2$  else  $exp_3$ 
```

```
case  $exp_1$  of  
  true  $\Rightarrow$   $exp_2$  |  
  false  $\Rightarrow$   $exp_3$ 
```

- The two expressions above are equivalent
- So **if-then-else** is really just a special case of **case**

Outline

- More pattern matching
- Function values and anonymous functions
- Higher-order functions and currying
- Predefined higher-order functions

the whole function (parameter, body, return).

Predefined Functions

- When an ML language system starts, there are many predefined variables
- Some are bound to functions:

function variable.

```
- ord; → holds function value  
val it = fn * char -> int  
- ~;  
val it = fn : int -> int
```

Defining Functions

- We have seen the **fun** notation for **defining new named functions**
- You can also **define new names for old functions**, using **val** just as for other kinds of values:

```
- val x = ~;  
val x = fn : int -> int  
- x 3;  
val it = ~3 : int
```

Function Values

- Functions in ML *do not have names*
- Just like other kinds of values, function values may be given one or more names by binding them to variables
- The **fun** syntax does two separate things:
 - Creates a new function value
 - Binds that function value to a name

Anonymous Functions

- ① call function
- ② pass a parameter
- ③ return function

□ Named function:

```
- fun f x = x + 2;  
val f = fn : int -> int  
- f 1;  
val it = 3 : intText
```

□ Anonymous function:

```
- fn x => x + 2;  
val it = fn : int -> int  
- (fn x => x + 2) 1;  
val it = 3 : int
```

The **fn** Syntax

- Another use of the match syntax
 $\langle \text{fun-expr} \rangle ::= \mathbf{fn} \langle \text{match} \rangle$
- Using **fn**, we get an expression whose value is an (anonymous) function
- We can define what **fun** does in terms of **val** and **fn**
- These two definitions have the same effect:
 - **fun f x = x + 2**
 - **val f = fn x => x + 2**

*- fn: int list * (int * int -> bool) -> int list*

Using Anonymous Functions

- One simple application: when you need a small function in just one place
- Without **fn**:

```
- fun intBefore (a,b) = a < b;  
val intBefore = fn : int * int -> bool  
- quicksort ([1,4,3,2,5], intBefore);  
val it = [1,2,3,4,5] : int list
```

- With **fn**:

```
- quicksort ([1,4,3,2,5], fn (a,b) => a<b);  
val it = [1,2,3,4,5] : int list  
- quicksort ([1,4,3,2,5], fn (a,b) => a>b);  
val it = [5,4,3,2,1] : int list
```

The **op** keyword

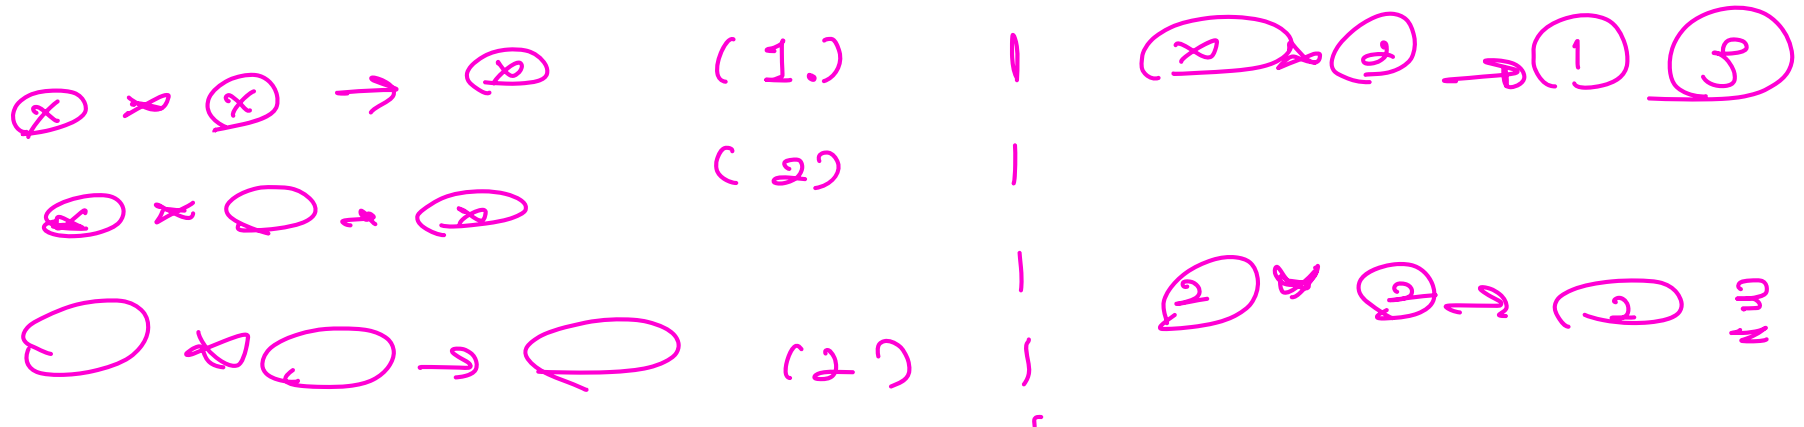

```
- op *;  
val it = fn : int * int -> int  
- quicksort ([1,4,3,2,5], op <);  
val it = [1,2,3,4,5] : int list
```

op keyword.

- Binary operators are special functions
- Sometimes you want to treat them like plain functions: to pass **<**, for example, as an argument of type **int * int -> bool**
- The keyword **op** before an operator gives you the underlying function

Outline

- More pattern matching
- Function values and anonymous functions
- Higher-order functions and currying
- Predefined higher-order functions

Higher-order Functions → order more than 1.

- Every function has an *order*:
 - A function that does not take any functions as parameters, and does not return a function value, has *order 1* (best case) (first order function)
 - A function that takes a function as a parameter or returns a function value has *order $n+1$* , where n is the order of its highest-order parameter or returned value
- The **quicksort** we just saw is a second-order function

Practice

What is the order of functions with each of the following ML types?

- 1 `int * int -> bool`
- 2 `int list * (int * int -> bool) -> int list`
2. `int -> int -> int`
- 2 `(int -> int) * (int -> int) -> (int -> int)`
- 3 `int -> bool -> real -> string`

What can you say about the order of a function with this type?

2 `('a -> 'b) * ('c -> 'a) -> 'c -> 'b`

Currying

- We've seen how to get two parameters into a function by passing a 2-tuple:

```
fun f (a,b) = a + b;
```

- Another way is to write a function that takes the first argument, and returns another function that takes the second argument:

```
fun g a = fn b => a+b;
```

- The general name for this is *currying*

Curried Addition

```
- fun f (a,b) = a+b;  
val f = fn : int * int -> int  
- fun g a = fn b => a+b;  
val g = fn : int -> int -> int  
- f(2,3);  
val it = 5 : int  
- g 2 3;  
val it = 5 : int
```

- Remember that function application is left-associative
- So `g 2 3` means `((g 2) 3)`

Advantages

- No tuples: we get to write `g 2 3` instead of `f(2, 3)`
- But the real advantage: we get to specialize functions for particular initial parameters

```
- val add2 = g 2;           already return a function
val add2 = fn : int -> int
- add2 3;
val it = 5 : int
- add2 10;
val it = 12 : int
```

Advantages: Example

- Like the previous **quicksort**
- But now, the comparison function is a first, curried parameter

```
- quicksort (op <) [1,4,3,2,5];  
val it = [1,2,3,4,5] : int list  
- val sortBackward = quicksort (op >);  
val sortBackward = fn : int list -> int list  
- sortBackward [1,4,3,2,5];  
val it = [5,4,3,2,1] : int list
```

*fn: (int * int -> bool) -> int list -> int list*

Multiple Curried Parameters

- Currying generalizes to any number of parameters

```
- fun f (a,b,c) = a+b+c;  
val f = fn : int * int * int -> int  
- fun g a = fn b => fn c => a+b+c;  
val g = fn : int -> int -> int -> int  
- f (1,2,3);  
val it = 6 : int  
- g 1 2 3;  
val it = 6 : int
```

Notation For Currying

- There is a much simpler notation for currying (on the next slide)
- The long notation we have used so far makes the little intermediate anonymous functions explicit

```
fun g a = fn b => fn c => a+b+c;
```

- But as long as you understand how it works, the simpler notation is much easier to read and write

Easier Notation for Currying

- Instead of writing:

```
fun f a = fn b => a+b;
```

- We can just write:

```
fun f a b = a+b;
```

- This generalizes for any number of curried arguments

```
- fun f a b c d = a+b+c+d;  
val f = fn : int -> int -> int -> int -> int
```

Outline

- More pattern matching
- Function values and anonymous functions
- Higher-order functions and currying
- **Predefined higher-order functions**

Predefined Higher-Order Functions

- We will use three important predefined higher-order functions:
 - `map`
 - `foldr`
 - `foldl`
- Actually, `foldr` and `foldl` are very similar, as you might guess from the names

The **map** Function

$(\text{int} \rightarrow \text{int}) \rightarrow \text{int_list} \rightarrow \text{int_list}$
 $(\text{int} \rightarrow \text{bool}) \rightarrow \text{int_list} \rightarrow \text{bool_list}$
 $(\text{int} \times \text{int}) \rightarrow \text{int} \rightarrow \text{int_list} \rightarrow \text{int_list}$

- Used to apply a function to every element of a list, and collect a list of results

```
- map ~ [1,2,3,4]; map = fn: int list → (int → int) → int list
val it = [~1,~2,~3,~4] : int list
- map (fn x => x+1) [1,2,3,4]; map = fn: int list → (int → int) → int list
val it = [2,3,4,5] : int list
- map (fn x => x mod 2 = 0) [1,2,3,4]; map = fn: int list → bool list
val it = [false,true,false,true] : bool list
- map (op +) [(1,2), (3,4), (5,6)];
val it = [3,7,11] : int list
```

The **map** Function Is Curried

```
- map;  
val it = fn : ('a -> 'b) -> 'a list -> 'b list  
- val f = map (op +);  
val f = fn : (int * int) list -> int list  
- f [(1,2), (3,4)];  
val it = [3,7] : int list
```

$(\text{int} \rightarrow \text{int}) \rightarrow \text{int list} \rightarrow \text{int list}$

$(\text{int} \rightarrow \text{bool}) \rightarrow \text{int list} \rightarrow \text{bool list}$

The **foldr** Function

- Used to combine all the elements of a list
- For example, to add up all the elements of a list **x**, we could write **foldr (op +) 0 x**
- It takes a function f , a starting value c , and a list $x = [x_1, \dots, x_n]$ and computes:

$$f(x_1, f(x_2, \dots f(x_{n-1}, f(x_n, c)) \dots))$$

- So **foldr (op +) 0 [1, 2, 3, 4]** evaluates as $1 + (2 + (3 + (4 + 0))) = 10$

Examples *Homework*

```
- foldr (op +) 0 [1,2,3,4];  
val it = 10 : int  
- foldr (op * ) 1 [1,2,3,4];  
val it = 24 : int  
- foldr (op ^) "" ["abc","def","ghi"];  
val it = "abcdefghi" : string  
- foldr (op ::) [5] [1,2,3,4];  
val it = [1,2,3,4,5] : int list
```

The **foldr** Function Is Curried

```
- foldr;  
val it = fn : ('a * 'b -> 'b) -> 'b -> 'a list -> 'b  
- foldr (op +);  
val it = fn : int -> int list -> int  
- foldr (op +) 0;  
val it = fn : int list -> int  
- val addup = foldr (op +) 0;  
val addup = fn : int list -> int  
- addup [1,2,3,4,5];  
val it = 15 : int
```

The `foldl` Function

- Used to combine all the elements of a list
- Same results as **`foldr`** in some cases

```
- foldl (op +) 0 [1,2,3,4];  
val it = 10 : int  
- foldl (op * ) 1 [1,2,3,4];  
val it = 24 : int
```

The **foldl** Function

- To add up all the elements of a list **x**, we could write **foldl (op +) 0 x**
- It takes a function f , a starting value c , and a list $x = [x_1, \dots, x_n]$ and computes:

$$f(x_n, f(x_{n-1}, \dots f(x_2, f(x_1, c)) \dots))$$

- So **foldl (op +) 0 [1,2,3,4]** evaluates as $4+(3+(2+(1+0)))=10$
- Remember, **foldr** did $1+(2+(3+(4+0)))=10$

The **foldl** Function

- **foldl** starts at the **left**, **foldr** starts at the **right**
- Difference does not matter when the function is associative and commutative, like **+** and *****
- For other operations, it does matter

```
- foldr (op ^) "" ["abc","def","ghi"] ;  
val it = "abcdefghi" : string  
- foldl (op ^) "" ["abc","def","ghi"] ;  
val it = "ghidefabcd" : string  
- foldr (op -) 0 [1,2,3,4] ;  
val it = ~2 : int  
- foldl (op -) 0 [1,2,3,4] ;  
val it = 2 : int
```
